Abstract

The normalized differential mean free path for volume scattering and the differential surface excitation probability for medium energy electrons travelling in Fe, Pd and Pt are extracted from Reflection Electron Energy Loss Spectra (REELS). This was achieved by means of a recently introduced procedure in which two REELS spectra taken under different experimental conditions are simultaneously deconvoluted. In this way, it is possible to obtain the unique reconstruction for the surface and volume single scattering loss distribution. The employed method is compared with a procedure that is frequently used for this purpose [Tougaard and Chorkendorff, Phys. Rev. B 35(1987)6570]. It is shown, both theoretically and through analysis of model spectra as well as experimental data that this method does not result in a *single* scattering loss distribution. Rather, it gives a mixture of surface, bulk and mixed scattering of any order.

1. INTRODUCTION

Quantitative analysis of reflection electron energy loss spectra (REELS) is important for surface science both in a practical and fundamental sense since such spectra contain valuable information on the response of a solid to an external electromagnetic perturbation. From the fundamental point of view it is desirable to extract the frequency (ω) and momentum (q) dependent dielectric function $\varepsilon(q, \omega)$ from experimental data, being the characteristic quantity for the susceptibility of the solid to polarize under bombardment with electromagnetic radiation [1–5]. For practical applications of electron spectroscopy, information about the differential distribution of energy losses in an individual loss process is a prerequisite for quantitative analysis of electron spectra [6, 7]. Such data can be directly extracted from REELS spectra and converted to dielectric data by invoking linear response theory.

The interaction of a reflected electron with a solid is quite complex since different types of collisions occur along the electron trajectory, and, furthermore, these scattering processes can occur repeatedly when the pathlength of the electron in the solid is long compared to the relevant mean free paths for scattering. The changes in the degrees of freedom of the electron are brought about by the interaction with the ionic subsystem, which mainly changes the direction of the particle in an elastic process and the interaction with the electronic subsystem, that gives rise to energy losses [7]. An energy loss process can be conceived as a deceleration of the probe electron by a polarization field that is set up in the solid by the response of the weakly-bound solid state electrons to the incoming electron [8]. This physical picture provides the connection between the dielectric function and the differential mean free path for inelastic electron scattering. Near a surface, the situation is further complicated through the occurrence of so-called surface excitations [9–18]. These are additional modes of the inelastic interaction that result from the boundary conditions of Maxwell’s equations near an interface between regions of different electromagnetic susceptibility. Surface excitations have a lower resonance frequency as compared to volume excitations and they occur on both sides of the solid-vacuum interface, but the probability for a surface excitation decays rapidly with the distance from the interface.

The question then arises how to extract the single scattering loss distribution for volume and surface excitations from an experimental spectrum. An important step to resolve this problem was taken some time ago by the pioneering work of Tougaard and Chorkendorff

[6] who found a simple deconvolution formula for REELS spectra. However, the physical model on which it is based completely ignores surface excitations. Furthermore, the basic process in a reflection experiment, multiple elastic scattering, was treated approximately, in the so-called P_1 -approximation, in which the expansion of the elastic scattering cross section in spherical harmonics is terminated after the first order [19]. In the medium energy range, the higher order phase shifts are by no means negligible [20] and consequently the P_1 -approximation does not provide a good physical basis to model REELS spectra.

Nonetheless, this formula is extensively used nowadays and it is commonly believed that the "effective" cross section that is extracted from a REELS spectrum in this way indeed represents a single scattering loss distribution, although the exact nature of this "effective" cross section has never been analyzed.

Some years later, several authors independently introduced a deconvolution procedure for REELS spectra in which elastic scattering is treated more realistically [9, 21]. Although this provides a better model to describe REELS spectra, the resulting deconvolution procedure leads to results that are very similar to those using Tougaard and Chorkendorffs algorithm. This has been attributed to the fact that surface excitations are also neglected in this procedure [9, 21, 22].

Recently, a deconvolution procedure was introduced that is based on a physical model that takes into account the multiple occurrence of surface excitations and deflections during elastic processes [23]. It is based on the simultaneous deconvolution of a set of two REELS spectra taken at different energies or geometrical configurations for which the relative contribution of surface and bulk excitations differs substantially. The main assumption in this procedure is that the *normalized* single scattering loss distributions for surface and volume scattering are independent of the energy of the probing electron and the angle of surface crossing [7, 23]. The essential difference with the earlier algorithms is that the latter are essentially effected by reversion of a univariate power series in Fourier space which has no unique solution if more than one kind of inelastic process takes place. The algorithm of Ref.[23] is based on reversion of a *bivariate* power series in Fourier space, which does provide the unique solution that is straightforward to interpret quantitatively.

The procedure based on a bivariate power series reversion was successfully applied to REELS spectra of Si, Cu and Au. The deconvolution procedure is quite involved, however, and the question therefore arises how seriously the deficiencies of the earlier methods

addressed above affect the results of the deconvolution. The present paper addresses this issue. The theory of signal generation in a REELS experiment as well as the different deconvolution procedures are reviewed. The reason for the good performance of the P_1 -approximation for *deconvoluting* spectra –in spite of the fact that it is not a good model to *simulate* REELS spectra– is elucidated. It is shown theoretically that the procedure of Tougaard and Chorkendorff does not result in a single scattering loss distribution. Rather, this procedure provides a mixture of surface and volume multiple scattering loss distributions and a contribution of mixed terms of any scattering order. Therefore, quantitative interpretation of the resulting loss distributions is troublesome.

Results of analysis of experimental spectra for Fe, Pd and Pt using a bivariate power series reversion are compared with results of the earlier algorithms. The bivariate power series reversion leads to true single scattering loss distributions that agree quantitatively with results based on the theory given by Tung [10] on an absolute scale. The main reason for the essential failure of any method based on a univariate power series reversion is that it does not eliminate mixed terms corresponding to electrons that experience both surface and volume excitations a certain number of times.

2. THEORETICAL

The theory of signal generation in REELS is discussed in detail in Ref [23], here we only present a brief synopsis. The flux of medium-energy electrons reflected from a solid surface consists of particles that have travelled different pathlengths in the solid. Since the probability for (multiple) scattering increases monotonically with the travelled pathlength, the outgoing flux consists of groups of electrons that have experienced a different number of inelastic processes. The net energy loss experienced after a given number of inelastic processes is subject to fluctuations that can be expressed in terms of a multiple self-convolution of the single scattering energy fluctuation distributions as follows from solution of a Boltzmann-type kinetic equation [24, 25]. The single scattering fluctuation distributions are given by the inverse differential mean free path for scattering. The normalized inverse differential mean free path for surface (subscript "s") and bulk (subscript "b") excitations will be denoted by $w_s(T)$ and $w_b(T)$ in the following. The normalized bulk mean free path is related to the absolute differential mean free path $W_b(T, E)$ via the total (integrated) inelastic mean free

path (IMFP) $\lambda_i(E)$:

$$w_b(T, E) = \lambda_i(E) W_b(T, E) \quad (1)$$

The normalized single scattering surface loss distribution is given in terms of the differential mean free path integrated over the part of the trajectory in the surface scattering zone, $W_s(T, E, \theta)$, as:

$$w_s(T, E, \theta) = \frac{W_s(T, E, \theta)}{\langle n_s(E, \theta) \rangle} \quad (2)$$

where the (dimensionless) quantity $\langle n_s(E, \theta) \rangle$ represents the average number of surface excitations in a single surface crossing along the polar direction $\cos \theta$. The dimensions of $w_s(T, E, \theta)$ and $w_b(T, E)$ are the same, reciprocal eV, while the dimensions of the quantities $W_s(T, E, \theta)$ and $W_b(T, E)$ are different, as is their physical meaning (see Ref. [23]). It turns out [7, 23, 26] that the *shape* of the single scattering loss distributions depends only very weakly on the energy and, in the case of surface excitations, on the surface crossing direction. Then the normalized single scattering loss distributions are only a function of the energy loss to a good approximation:

$$\begin{aligned} w_b(T, E) &\simeq w_b(T) \\ w_s(T, E, \theta) &\simeq w_s(T) \end{aligned} \quad (3)$$

Formulae to establish the differential inverse inelastic mean free path (DIIMFP) $W_b(T, E)$ and the differential surface excitation probability (DSEP) $W_s(T, E, \theta)$ can be found in many instances in the literature, in the present work the expressions given in Ref. [10] will be employed. The differential mean free path for inelastic scattering is frequently referred to in the literature as "cross section" but one should keep in mind that in doing so, the solid state character of the medium is completely ignored, which is certainly not justifiable for medium energy electrons travelling in solids.

In the following, the fluctuation distributions after n_s -fold surface and n_b -fold volume scattering will be denoted by $w_s^{(n_s)}$ and $w_b^{(n_b)}$, respectively, where the exponent in brackets $(^{(n)})$ indicate the $n - 1$ -fold selfconvolution of the respective quantity. Multiplying these with the relative number of electrons that arrive in the detector after suffering the corresponding number of energy losses, the so-called partial intensities, α_{n_b, n_s} , and summing over all scattering orders, one obtains the following expression for the loss spectrum $y_L(T)$:

$$y_L(T) = \sum_{n_b=0}^{\infty} \sum_{n_s=0}^{\infty} \alpha_{n_b, n_s} w_b^{(n_b)}(T') \otimes w_s^{(n_s)}(T - T') \quad (4)$$

where the symbol $\otimes$ denotes a convolution over the energy loss T . The spectrum $y_L(T)$ represents the loss spectrum divided by the area of the elastic peak and from which the elastic peak is removed by choosing $\alpha_{n_b=0, n_s=0} = 0$.

The reduced partial intensities for surface and bulk scattering are uncorrelated:

$$\alpha_{n_b, n_s} = \alpha_{n_b} \times \alpha_{n_s} \quad (5)$$

since the part of the trajectory in the surface scattering zone is rectilinear to a good approximation [26]. Although (small) effects of deflections in the surface scattering zone have been experimentally observed for a rather pathological case [27], this approach nonetheless has proven to constitute an effective approximation [26–29].

The reduced bulk partial intensities are given by the well known equation [7, 30]

$$\alpha_{n_b} = \frac{\int_0^\infty W_{n_b}(s)Q(s)ds}{\int_0^\infty W_0(s)Q(s)ds} \quad (6)$$

Here $Q(s)$ is the distribution of pathlengths and $W_n(s)$ is the stochastic process for multiple scattering, which, in the quasielastic regime, is given by [30]:

$$W_n(s) = \left(\frac{s}{\lambda_i}\right)^n \frac{e^{-s/\lambda_i}}{n!} \quad (7)$$

The partial intensities for surface scattering, A_{n_s} , follow Poisson statistics, implying that the reduced partial intensities $\alpha_{n_s} = A_{n_s}/A_{n_s=0}$ are given by:

$$\alpha_{n_s} = \frac{\langle n_s \rangle^{n_s}}{n_s!} \quad (8)$$

with $\langle n_s \rangle = \langle n_s^i \rangle + \langle n_s^o \rangle$ representing the sum of the average number of surface excitations along the in and outgoing part of the trajectory. Surface excitations along the in- and outgoing part of the trajectory are combined in Eqn. (4) by assuming that the shape of the *normalized* distribution of surface energy losses is independent of the surface crossing direction θ [23].

3. DECOMPOSITION OF REELS SPECTRA

3.1. I: reversion of a univariate power series within the P_1 -approximation (Ref. [6]) .

In the method of Tougaard and Chorkendorf [6] two approximations are made: (1) surface excitations are neglected; and (2) multiple elastic scattering is treated in the so-called P_1 -approximation. Based on these starting assumptions, a simple deconvolution formula was derived that is frequently used also in situations where surface excitations dominate the low energy loss region of a spectrum. It is commonly believed that in such cases the method provides an "effective" *single* scattering loss distribution i.e. some kind of linear combination of $w_s(T)$ and $w_b(T)$ but this has never been proved.

In the P_1 -approximation, the elastic scattering cross section that enters the collision term of a Boltzmann-type kinetic equation for the particle transfer, is expanded in spherical harmonics and the expansion is terminated after the first order. In this way, a tractable analytic solution for the reflection problem has been found [31]. The expression for the pathlength distribution $Q_{P_1}(s)$ reads:

$$Q_{P_1}(s) \propto \exp(-s/L) \quad (9)$$

where the characteristic length L is about twice the transport mean free path $L \simeq 2\lambda_{tr}$. Inserting this result into Equation (6), the bulk partial intensities are found as:

$$\alpha_{n_b}^{P_1} = \kappa^{n_b} \quad (10)$$

where $\kappa = L/(L + \lambda_i)$.

When surface excitations are neglected, Equation (4) simplifies to:

$$y_L(T) = \sum_{n_b=0}^{\infty} \alpha_{n_b} w_b^{(n_b)}(T) \quad (11)$$

Convolving this equation with $\alpha_2/\alpha_1 w_b(T)$ and subtracting the result from Equation (11) gives:

$$y_L(T) - \frac{\alpha_2}{\alpha_1} w_b(T') \otimes y_L(T - T') = \alpha_1 w_b(T) + \sum_{n=3}^{\infty} \left(\alpha_n - \frac{\alpha_2}{\alpha_1} \alpha_{n-1} \right) w_b^{(n)} \quad (12)$$

For a sequence of partial intensities of the form $\alpha_n = \kappa^n$, all terms in the sum on the right hand side vanish. Therefore, within the P_1 -approximation for elastic scattering, the *exact*

solution of Equation (11) is:

$$\frac{\lambda_i L}{\lambda_i + L} W_b(T) = y_L(T) - \frac{\lambda_i L}{\lambda_i + L} W_b(T') \otimes y_L(T - T'), \quad (13)$$

where Equation (1) has been used. This is the deconvolution formula of Tougaard and Chorkendorff for which a simple recursive scheme was proposed by these authors [6].

3.2. II: exact reversion of a univariate power series (Ref. [9] and [21])

Although Equation (13) is the exact solution of Equation (11) in the P_1 -approximation, its validity has been questioned by several authors [9, 21], since the P_1 -approximation does not provide an accurate model for the *simulation* of REELS spectra. This becomes evident on comparing the partial intensities in the P_1 -approximation, with more realistic results based on the Mott cross section for elastic scattering. Results of such calculations are displayed in Figure 1 for electrons travelling in Fe for several energies, along with the corresponding Mott cross section [32]. It is seen that the partial intensities in the P_1 -approximation are qualitatively different from the more realistic results based on the Mott cross section. This is caused by the influence of the shape of the cross section on the sequence of partial intensities [20, 33]. Realizing that the partial intensities represent the number of electrons arriving in the detector after a given number of inelastic processes, it is clear that the P_1 -approximation is not a good approach for quantitative simulation of REELS spectra (see Figure 3a below).

The exact solution of Equation (11) for an arbitrary sequence of partial intensities, not necessarily of the form $\alpha_n = \kappa^n$, was found independently by Vicanek [9] and the present author [21]:

$$w_b(T) = \sum_{q=1}^{\infty} u_q y_L^{(q)}(T) \quad (14)$$

The coefficients u_q in this solution are functions of the partial intensities, that are derived in Appendix I. This procedure was successfully applied to experimental spectra given by a univariate power series in Fourier space, obtained by eliminating multiple volume scattering from them prior to application of Eqn. (14) [26, 28].

For partial intensities in the P_1 -approximation ($\alpha_{n_b} = \kappa^{n_b}$), the coefficients u_q assume a particularly simple form:

$$u_q = \frac{(-1)^{q+1}}{\kappa} \quad (15)$$

Therefore, a non-recursive alternative representation of Eqn. (13) is given by:

$$\kappa w_b(T) = \sum_{q=1}^{\infty} (-1)^{q+1} y_L^{(q)}(T), \quad (16)$$

which is sometimes useful for a theoretical analysis, although Eqn. (13) is simpler for practical applications.

3.3. III: exact reversion of a bivariate power series (Ref. [23])

The above deconvolution procedures proceed via reversion of a univariate power series in Fourier space. However, when more than one type of scattering contributes to the spectrum, the spectrum is represented by a bivariate power series in Fourier space and, in consequence, a univariate power series reversion does not give the unique solution for the involved mean free paths. This problem can be resolved [23] by simultaneously deconvolving a set of two spectra taken at different energies or scattering geometries, leading to a different sequence of partial intensities. In doing so, it is assumed that the *normalized* differential mean free path for volume and surface scattering is independent of the energy and scattering geometry, i.e. that the normalized mean free paths in the two spectra are identical [see Eqn. (3)]. This turns out to be a very reasonable approximation [7, 23]. Then, the unique solution for the mean free path for surface and bulk scattering is given by the expression:

$$\begin{aligned} w_b(T) &= \sum_{p=0}^{\infty} \sum_{q=0}^{\infty} u_{p,q}^b y_{L,1}^{(p)}(T') \otimes y_{L,2}^{(q)}(T - T') \\ w_s(T) &= \sum_{p=0}^{\infty} \sum_{q=0}^{\infty} u_{p,q}^s y_{L,1}^{(p)}(T') \otimes y_{L,2}^{(q)}(T - T') \end{aligned} \quad (17)$$

where the coefficients u_{pq}^b and u_{pq}^s are again functions of the partial intensities. The algorithm to obtain these coefficients is given in Appendix II.

4. RESULTS AND DISCUSSION

In order to compare the procedures described above, they were first applied to results of model calculations (as described in Ref. [23]) and subsequently experimental data were deconvoluted with the method of Tougaard and Chorkendorff (TC) and with the reversion of a bivariate power series.

The procedure used to acquire the experimental data has been described in detail before [33]. REELS data for Fe, Pd and Pt were measured in the energy range between 300 and 3400 eV for normal incidence and an off-normal emission angle of 60° , using a hemispherical analyzer operated in the constant analyzer energy mode giving a width of the elastic peak of 0.7 eV. Count rates in the elastic peaks were kept well below the saturation count rate of the channeltrons and a dead time correction was applied to the data. For each material the optimum energy combination for the retrieval procedure of two loss spectra was determined by inspection of the partial intensities. For most materials the optimum energy combination was (1000-3000 eV) [23].

All simulated data were calculated for the scattering geometry used in the experiment with the method described in Refs. [23, 33]. In a first step, simulated spectra were generated neglecting surface excitations and using the bulk partial intensities calculated within the P_1 -approximation. In this case method I exactly returned the model DIIMFP. When the more realistic partial intensities based on the Mott cross section are used (see Figure 1), the simulated spectra are significantly different. However, the results of method I and II for the shape of the retrieved DIIMFP was indistinguishably similar, the only difference is that the absolute value of the DIIMFP differs since the first and second order partial intensities are different. The reason why both methods give essentially the same results for the shape of the DIIMFP is easy to understand on inspection of the partial intensities in Figure 1. Although the sequence of partial intensities obtained from MC calculations is qualitatively different from the one obtained in the P_1 -approximation, the MC-partial intensities for the two energies shown are also to a good approximation of the form $\alpha_n = \kappa^n$ (with a different value for κ), at least for the first few scattering orders $n \sim 1 - 5$. Therefore, method I essentially results in the correct deconvolution for any spectrum that can be represented as a univariate power series of the DIIMFP in Fourier space. This is true for any realistic sequence of partial intensities for the first few scattering orders, except for some really pathological cases [21].

However, when method I is applied to simulated data in which surface excitations are not ignored, the results are no longer interpretable in a straightforward way. This can be seen in Figure 2 that shows model calculations for loss spectra with plasmon peaks modelled by Gaussian peak shapes (15 eV for the surface- and 25 eV for the bulk plasmon). The width of the plasmon loss peaks was taken to be 0.4 eV in (a) and 2.4 eV in (b). The retrieved

loss distributions clearly contain significant intensity from higher order scattering.

This becomes understandable by analyzing the loss distribution retrieved by method I. In order to do so, the spectrum [Eqn. (4)] is inserted into Eqn. (16), giving:

$$\kappa w^{TC}(T) = \alpha_{1,0}w_b(T) + \alpha_{0,1}w_s(T) - \alpha_{1,1}w_b(T') \otimes w_s(T - T') - \alpha_{2,0}w_s^{(2)}(T) + \mathcal{O}(w^{(3)}) \quad (18)$$

where Eqns. (5) and (8) were used. Thus, it is found that the loss distribution of Tougaard and Chorkendorff contains a negative contribution equal to the second order mixed and surface scattering term. This is clearly observed in Figure 2a. It is also seen that the higher orders decrease rapidly with the scattering order. Since the average number of surface excitations is usually quite small compared to unity, the contribution of surface excitations may become negligible for high enough energies, but the essential point is that the second order mixed term is always appreciable in magnitude since it remains comparable to the single scattering partial intensities for surface (and bulk) scattering. This finding also explains the spurious negative excursions for energies corresponding to one surface and one bulk loss in the retrieved loss distributions in Ref. [6] and similar works published in the past twenty years.

Similar results were obtained for more realistic simulations for 500 eV electrons in Fe, shown in Figure 3. In Figure 3a the dotted curve represents the simulation in the P_1 -approximation, while the dashed curve is based on Monte Carlo (MC) calculations for the pathlength distribution from which the partial intensities are derived via Equation (6). The latter are seen to agree better with the experimental data (represented by the noisy solid curve). The reason is that the realistic Mott cross section for elastic scattering can not be described by a first order Legendre polynomial, as implicitly assumed in the P_1 -approximation (see Figure 1a). In Figure 3b, the distribution retrieved with method I is shown as the solid curve and is compared with the single surface and volume scattering contribution to the spectrum, represented by the chain-dashed and long-dashed curves, respectively. The short dashed curve is the total single scattering distribution of the model spectrum, i.e. $\alpha_{1,0}w_b(T) + \alpha_{0,1}w_s(T)$. It is seen that the retrieved loss distribution is lower than the single scattering loss distribution and that it can *not* be represented by any linear combination of the single scattering contributions. Thus, the method of Tougaard and Chorkendorff never gives a *singlescattering* loss distribution when surface scattering is not negligible.

Finally, the method suggested by Chen [22] deserves to be addressed in this context. This author proposed to extract the DIIMFP and the DSEP by using the "effective" cross section of Tougaard and Chorkendorff obtained from REELS spectra taken at two different energies. This method is thus experimentally similar to the bivariate power series reversion, however, the results are quite different, as will be shown below. To eliminate the first order bulk contribution, giving a retrieved distribution with the first order DSEP as the leading term, two Tougaard-Chorkendorff cross sections w_1^{TC} and w_2^{TC} are subtracted from each other after one of them is multiplied with $\nu = \alpha_{1,0}/\beta_{1,0}$. Here α_{n_b,n_s} are the partial intensities of spectrum 1 and β_{n_b,n_s} are the partial intensities of spectrum 2. This gives:

$$\kappa_1 w_1^{TC}(T) - \kappa_2 w_2^{TC}(T) = \Delta_{1,0} w_b(T) + \Delta_{0,1} w_s(T) - \Delta_{1,1} w_b(T') \otimes w_s(T - T') - \Delta_{2,0} w_s^{(2)}(T) + \mathcal{O}(w^3) \quad (19)$$

where $\Delta_{n_b,n_s} = \alpha_{n_b,n_s} - \nu \beta_{n_b,n_s}$. It is seen, also in this case, that the second order mixed term is always of the same order of magnitude as the first order surface term in the resulting (difference) spectrum:

$$-\frac{\Delta_{1,1}}{\Delta_{0,1}} \simeq -1, \quad (20)$$

So that in this method the mixed terms also make it impossible to recover the single scattering loss distributions from two "effective" cross sections obtained from REELS spectra taken at two energies (or scattering geometries). The analysis of Chen [22] is quite different from the present one. In the work by this author, the mixed terms are "eliminated" by replacing the Fourier transform of the bulk DIIMFP ($\tilde{\mu}_B^0(s)$ in the notation of that paper) in Eq.(45) by the same quantity in real space in Eqns. (46)-(51). In this way this procedure ignores the mixed terms, but unfortunately, they are of the same order of magnitude as the first order surface and bulk term.

The result of the retrieval using the bivariate power series reversion is compared in Figure 3c (dashed lines) with the model DIIMFP and DSEP for 3000 eV (solid lines). In this case the retrieved distributions for surface and bulk scattering are separated and are very similar to the model distributions. The differences that can be observed are due to the assumption that the normalized DIIMFP and DSEP are independent of the energy of the probing electron and the direction of surface crossing. Although this is a good approximation, it is not exactly true and hence the retrieved distributions agree with the model loss distribution (for one energy) within the accuracy of this approximation. If the model

DIIMFP and DSEP are taken to be the same for both energies and for the incoming and outgoing direction of surface crossing, the retrieved distributions *exactly* agree with the model distributions, since Eqn. (17) is the *exact* solution of Eqn. (4).

Application of Tougaard and Chorkendorffs method to the 1 keV experimental spectra of Fe, Pd and Pt is shown in Figure 4 as open circles. The dashed and dash-dotted curves represent the theoretically expected contribution of surface and volume scattering, the solid curve is their sum. For all three materials, the experimentally retrieved loss distribution in Figure 4 is seen to be significantly lower than the total single scattering contribution (solid curves) for energies $\lesssim 80$ eV while for higher energy losses they become similar to the theoretically expected result. This makes it clear that the loss distributions retrieved by the method of Tougaard and Chorkendorff are not a linear combination of the single scattering surface and volume loss distributions being attributable (mainly) to the negative second order mixed term, as discussed above. Thus, although the retrieval of these data from experimental results is very simple, the usefulness of this procedure is questionable since quantitative interpretation of the results is by no means straightforward.

The method of reversion of a bivariate power series in Fourier space is illustrated in Figure 5 for Fe (1000-3000 eV), Pd (500-3400 eV) and Pt (1000-3000 eV). Figure 5a compares the measured loss spectra (i.e. the spectra after division by the area of the elastic peak and after removal of the latter) as noisy solid curves with simulated spectra (smooth solid curves). Reasonable agreement between simulation and experiment is seen in all cases, but significant deviations can also be observed. For example, the ionization edges at ~ 60 eV are not exactly reproduced by the simulation in all cases. This is attributable to the fact that it is difficult to fit ionization edges with a Drude-Lindhard type expansion of the dielectric function [10].

In Figure 5b and c the DSEP and DIIMFP retrieved with the bivariate power series reversion are represented by the open circles and compared with result based on the theory of Tung and coworkers [10] (solid curves). In all cases the agreement is quite good, except in the vicinity of ionization edges. Furthermore, the main feature in the DIIMFP of Fe is a bit sharper than predicted by theory and the DSEP for Pd is significantly higher in the energy range between 10–30 eV. Note that the retrieved distributions were not scaled in any way, the normalized loss distributions are compared on an absolute scale.

The DSEP always exhibits a negative excursion for an energy corresponding approximately to the average volume loss. This feature, that has a clear physical explanation [26],

is also seen in the theoretical results and is a consequence of the coupling of surface and bulk excitations that are essentially different (orthogonal) modes of the inelastic interaction. The coupling term is included in the DSEP, as defined in the present work [23, 27], and it is always negative. So the DSEP is in fact a difference of two probabilities, the pure surface excitation term and the coupling term that takes into account the orthogonality of the surface and bulk modes, and the resulting DSEP exhibits a negative excursion whenever the coupling term exceeds the pure surface term.

Finally, in Figure 6 the present results for the volume single scattering loss distribution is compared with results based on optical data from various sources in the literature [1, 2, 10, 34]. The literature data exhibit significant discrepancies. For Pd, the present results agree well with those of Tung [10] for energies below ~ 50 eV. For Pt, the present results excellently match the data by Tanuma [34] and Palik [1]. In both cases, the ionization edge is more pronounced in the present data. This feature is well reproduced by first principles calculations based on density functional theory calculations beyond the ground state for both materials (dash-dotted lines) [2].

5. SUMMARY AND CONCLUSIONS

The single scattering loss distribution for inelastic electron scattering was extracted from experimental data for Fe, Pd and Pt. This was done by means of a recently proposed procedure [23] in which it is assumed that the *normalized* differential mean free path for inelastic scattering (DIIMFP) does not depend on the energy of the probing electron. Furthermore, it is assumed that the *normalized* differential surface excitation probability (DSEP) does not depend on the surface crossing direction and the primary energy. Under these assumptions, a set of two spectra with a different sequence of partial intensities can be simultaneously deconvoluted to give the normalized true single scattering loss distributions. The deconvolution procedure proceeds via the reversion of a bivariate power series in Fourier space. Experimentally, two spectra with a different sequence of partial intensities can be obtained by measuring the loss spectrum at two different energies, as studied in the present work, or, alternatively, for two different scattering geometries. The latter case, which was not studied here, is a bit more demanding experimentally, but has the great advantage that the DIIMFP and DSEP of the two spectra are indeed identical. In other words, it is then only the angu-

lar dependence of the DSEP (for the in- and outgoing beam) that may slightly distort the deconvolution results. However, the present results based on spectra taken at two different energies also compare very well with theoretical results since the energy dependence of the normalized single scattering loss distributions is quite weak in reality.

A detailed comparison was made with earlier methods based on reversion of a univariate power series. The most well known and frequently used deconvolution procedure by Tougaard and Chorkendorff [6] belongs to this class of procedures. It was shown, both theoretically and on the basis of model calculations, that when such a method is applied to a spectrum described by a bivariate power series (in the surface and volume single scattering loss distribution), it results in a not very well defined mixture of multiple volume, surface and mixed scattering terms. In particular, the second order mixed term (corresponding to electrons that experience one surface and one volume energy loss) gives a strong negative contribution in the resulting loss distribution. This explains the spurious negative excursion at energies corresponding to one bulk and one surface loss in spectra deconvoluted by the method of Tougaard and Chorkendorff that have been published over the past twenty years (see e.g., Ref. [6]).

Finally, and most importantly, the above findings confirm the theoretical model for REELS based on a bivariate power series in the DSEP and the DIIMFP in Fourier space [23] with unprecedented detail.

The author is grateful to Dr. S. Tanuma (Ref. [34]) and Dr. C. Ambrosch-Draxl (Ref. [2]) for making their optical data available before publication. Financial support of the present work by the Austrian Science Foundation FWF through Project No. P15938-N02 is gratefully acknowledged

7. APPENDIX

7.1. Reversion of a univariate powers series

We consider the loss spectrum y_L written as a power series of the variable w in Fourier space (i.e. a multiple self-convolution in real space):

$$y_L(T) = \sum_{n=0}^{\infty} \alpha_n w^{(n)}(T) \quad (21)$$

where $\alpha_0 = 0$ since it is assumed that the elastic peak has been removed from the spectrum. Since the leading term in y_L is the first power of w , the solution must be of the form:

$$w(T) = \sum_{q=1}^{\infty} u_q y_L(T)^{(q)}. \quad (22)$$

Inserting Eq.21 into this ansatz one finds:

$$w(T) = \sum_{q=1}^{\infty} u_q \left\{ \sum_{n=1}^{\infty} \alpha_n w^{(n)}(T) \right\}^{(q)}, \quad (23)$$

and, equating coefficients of equal powers in the above equation:

$$1 = u_1 \alpha_1$$

$$0 = u_1 \alpha_2 + u_2 \alpha_1 \alpha_1$$

$$0 = u_1 \alpha_3 + u_2 (\alpha_1 \alpha_2 + \alpha_2 \alpha_1) + u_3 \alpha_1 \alpha_1 \alpha_1$$

$$0 = u_1 \alpha_4 + u_2 (\alpha_2 \alpha_2 + \alpha_1 \alpha_3 + \alpha_3 \alpha_1) + u_3 (\alpha_2 \alpha_1 \alpha_1 + \alpha_1 \alpha_2 \alpha_1 + \alpha_1 \alpha_1 \alpha_2) + u_4 \alpha_1 \alpha_1 \alpha_1 \alpha_1$$

...

the solution for the unknown coefficients u_q is easily seen and can be found in any standard textbook [35, 36] in a slightly different and more explicit albeit less general form. The interesting point in the present notation, however, is that the subscripts in the coefficients of u_q in the above equations represent the sum of all permutations of the partitions of n (the order) with q factors in them.

7.2. Reversion of a bivariate power series.

When *two* loss spectra with a different sequence of partial intensities are measured,

$$\begin{aligned} y_{L,1}(T) &= \sum_{n_s=0}^{\infty} \sum_{n_b=0}^{\infty} \alpha_{n_s,n_b} w_b^{(n_b)}(T') \otimes w_s^{(n_s)}(T - T') \\ y_{L,2}(T) &= \sum_{n_s=0}^{\infty} \sum_{n_b=0}^{\infty} \beta_{n_s,n_b} w_b^{(n_b)}(T') \otimes w_s^{(n_s)}(T - T'), \end{aligned} \quad (24)$$

with $\alpha_{0,0} = \beta_{0,0} = 0$, a unique solution for the unknowns $w_s(T)$ and $w_b(T)$ can be established by reversion of this bivariate power series (in Fourier space).

Formally, the reversion of this bivariate power series is effected by the expansion:

$$\begin{aligned} w_b(T) &= \sum_{p=0}^{\infty} \sum_{q=0}^{\infty} u_{p,q}^b y_{L,1}^{(p)}(T') \otimes y_{L,2}^{(q)}(T - T') \\ w_s(T) &= \sum_{p=0}^{\infty} \sum_{q=0}^{\infty} u_{p,q}^s y_{L,1}^{(p)}(T') \otimes y_{L,2}^{(q)}(T - T') \end{aligned} \quad (25)$$

with $u_{0,0}^b = u_{0,0}^s = 0$. This can be seen by substituting Equation (24) back into Equation (25) and equating coefficients of equal powers of w_b and w_s . This gives the equations for the unknown coefficients $u_{p,q}^b$ and $u_{p,q}^s$.

In doing so, one is faced with the problem of evaluating the convolution of $y_{L,1}^{(p)}(T)$ with $y_{L,2}^{(q)}(T)$ that can be expressed as:

$$y_{L,1}^{(p)}(T') \otimes y_{L,2}^{(q)}(T - T') = \sum_{n_s=0}^{\infty} \sum_{n_b=0}^{\infty} \gamma_{p,q,n_b,n_s} w_b^{(n_b)}(T') \otimes w_s^{(n_s)}(T - T') \quad (26)$$

The coefficients γ_{p,q,n_b,n_s} are found to be given by:

$$\gamma_{p,q,n_b,n_s} = (\alpha_p, \beta_q)_{(n_b,n_s)}^{(p+q)} \quad (27)$$

These coefficients are equal to the sum of all possible terms with p factors in $\alpha_{k,l}$ and q factors in $\beta_{m,n}$, whose indices "add up" to the target index combination $(n_s, n_b) = (k + m, l + n)$.

For example:

$$\begin{aligned} (\alpha_2)_{(2,1)}^{(2)} &= \alpha_{1,0}\alpha_{1,1} + \alpha_{0,1}\alpha_{2,0} + \alpha_{1,1}\alpha_{1,0} + \alpha_{2,0}\alpha_{0,1} \\ (\alpha_1, \beta_2)_{(1,2)}^{(3)} &= \alpha_{0,1}\beta_{0,1}\beta_{1,0} + \alpha_{0,1}\beta_{1,0}\beta_{0,1} + \alpha_{1,0}\beta_{0,1}\beta_{0,1} \end{aligned} \quad (28)$$

Obviously, one has

$$\gamma_{p,q,n_b,n_s} = 0 \quad \text{for all } p + q > n_s + n_b \quad (29)$$

since the target index combination (n_s, n_b) can only be produced by a number of factors less than or equal to $(n_s + n_b)$ when $\alpha_{0,0} = \beta_{0,0} = 0$ [see Equation (24)]. Furthermore, one has:

$$\begin{aligned}\gamma_{1,0,n_b,n_s} &= \alpha_{n_b,n_s} \\ \gamma_{0,1,n_b,n_s} &= \beta_{n_b,n_s}\end{aligned}\tag{30}$$

Based on these guidelines, the coefficients γ_{p,q,n_b,n_s} can readily be established by means of a recursive algorithm for any sequence of partial intensities α_{n_b,n_s} and β_{n_b,n_s} .

Inserting Equation (24) into Equation (25) and equating coefficients, one finds a set of two equations with two unknowns for the first order bulk coefficients:

$$\begin{aligned}1 &= \sum_{p=0}^{\infty} \sum_{q=0}^{\infty} u_{p,q}^b \gamma_{p,q,1,0} = u_{0,1}^b \beta_{1,0} + u_{1,0}^b \alpha_{1,0} \\ 0 &= \sum_{p=0}^{\infty} \sum_{q=0}^{\infty} u_{p,q}^b \gamma_{p,q,0,1} = u_{0,1}^b \beta_{0,1} + u_{1,0}^b \alpha_{0,1}\end{aligned}\tag{31}$$

The solution is:

$$\begin{aligned}u_{1,0}^b &= \frac{\beta_{0,1}}{\beta_{0,1}\alpha_{1,0} - \beta_{1,0}\alpha_{0,1}} \\ u_{0,1}^b &= \frac{\alpha_{0,1}}{\alpha_{0,1}\beta_{1,0} - \alpha_{1,0}\beta_{0,1}}\end{aligned}\tag{32}$$

Similarly, for the first order surface coefficients one finds:

$$\begin{aligned}u_{1,0}^s &= \frac{\beta_{1,0}}{\beta_{1,0}\alpha_{0,1} - \beta_{0,1}\alpha_{1,0}} \\ u_{0,1}^s &= \frac{\alpha_{1,0}}{\alpha_{1,0}\beta_{0,1} - \alpha_{0,1}\beta_{1,0}}\end{aligned}\tag{33}$$

The equation determining the higher order $(p + q > 1)$ coefficients

$$0 = \sum_{p=0}^{\infty} \sum_{q=0}^{\infty} u_{p,q} \gamma_{p,q,n_b,n_s}\tag{34}$$

can be split into two parts by using property (29), changing the order of the summation and writing:

$$0 = \sum_{p=0}^{n_s+n_b-1} \sum_{q=0}^p u_{q,p-q} \gamma_{q,p-q,n_b,n_s} + \sum_{p=0}^{n_s+n_b} u_{p,n_s+n_b-p} \gamma_{p,n_b+n_s-p,n_b,n_s}\tag{35}$$

The first term represents a $(n_s + n_b + 1)$ -dimensional vector containing the coefficients $u_{p < n_b, q < n_s}$, which have been established during the previous step of the algorithm. The latter

term is the product of a square matrix with the same dimension and the unknown vector $(u_{0,n_b+n_s}, u_{1,n_b+n_s-1}, u_{2,n_b+n_s-2}, \dots, u_{n_b+n_s,0})$. Thus, for each value of $n_b + n_s$, the corresponding coefficients are obtained by solution of a system of $n_b + n_s + 1$ linear equations with as many unknowns. Consecutively performing this procedure for values of the total scattering order $n_b + n_s = 1, 2, \dots, n_{max}$, where n_{max} is the collision order where convergence of the series Equation (25) is attained, leads to the desired coefficient matrices $u_{p,q}^b$ and $u_{p,q}^s$. Note that Eqns. (34) and (35) are identical for the surface and bulk coefficients, only the calculation for the first order term is different [see Eqns. (32) and (33)]. Although faster algorithms for reversion of multivariate power series are available [37–39], these are quite complex and were not considered here since convergence of the proposed algorithm is typically attained for $n_{max} \leq 7$ for energy loss ranges extending up to 100 eV.

FIG. 1: (a) Differential Mott cross section for elastic scattering for Fe for two electron energies. (b) Reduced partial intensities α_{n_b} for volume scattering for several energies in Fe. Solid curves: Monte Carlo calculations based on the Mott scattering cross section. Dashed curves: P_1 -approximation (Equation (10))

FIG. 2: Simulated spectra (solid lines) for a model DIIMFP and DSEP represented by a Gaussian peak shape with a mean energy loss of 25 and 15 eV, respectively. The dashed curves are the result of application of Tougaard and Chorkendorff's algorithm Eqn. (13). It is seen that the latter does not eliminate the higher order terms. (a.) a model plasmon width of 0.4 eV was used. (b) a model plasmon width of 2.4 eV was used.

FIG. 3: (a) experimental REELS spectrum for 3000 eV-electrons backscattered from an Fe-surface (solid curve), spectrum simulated with Equation (4) based on the Mott cross section for elastic scattering (dashed curve) and simulated spectrum within the P_1 -approximation for elastic scattering (dotted curve). (b) loss distribution retrieved from the simulated spectrum in (a) based on the Mott cross section for elastic scattering using the Method of Tougaard and Chorkendorff [6] (solid curve). The long-dashed curve represents the single volume scattering contribution of the simulated spectrum, the dash-dotted curve is the contribution of single surface scattering. The short-dashed curve is the total single scattering contribution in the spectrum in (a). (c.) normalized DIIMFP and DSEP retrieved from the simulated spectra in Figure 5(a) using the bivariate power series reversion [23] (dashed curves) compared with the DIIMFP and DSEP used in the simulation (solid curves).

FIG. 4: Loss distribution obtained with the method of Tougaard and Chorkendorff [6] (open circles). The dash-dotted and dashed curves are the normalized DIIMFP and DSEP calculated with the formulae in [10] and multiplied with the according single scattering partial intensities, the solid curve represents their sum. In all cases, it can be seen that the retrieved spectrum is *nota* linear combination of the single scattering terms. (a) Fe; (b) Pd; (c) Pt.

FIG. 5: (a) Measured energy loss spectra for Fe, Pd and Pt for the energies indicated in the legend after removal of the elastic peak (noisy curves). The smooth curves are the simulated loss spectra using theoretical shapes for the DSEP and DIIMFP. (b) Retrieved normalized DSEP (open circles). (c) Retrieved normalized DIIMFP (open circles). The solid curves in (b) and (c) represent the result based on the theory by Tung and coworkers [10].
